Dating Potential in Propensity Scores:

Using Causal Inference to Explore How Educational-Attainment Affects

Seeking Partners Who Want Children

December 11, 2023

MOTIVATION

On Friday, June 24, 2022, the United States Supreme Court ruled in *Dobbs v. Jackson Women's Health Organization* that abortion is not a constitutional right, reversing the 50 years of precedent set by *Roe v. Wade* that the procedure was legal and protected by federal law. (Totenberg, 2022). Effectively, the ruling leaves the decision to make abortion legal (or not) up to the individual states.

Commented [MS1]: NPR, nbc news

In an instant, this right of bodily autonomy in the United States of American was gone or in jeopardy. Since then, millions of people have grown more self-conscious of their lifestyles and behaviors that may put them into confusing and potentially dangerous legal territory, especially depending on where they live. This includes in choosing potential romantic partners. In Indiana University's Kinsey Institute and Match[.com]'s 2022 "Singles in America" study, 5000 U.S. single adults between age 18 and 98 were asked about their views about dating (Krause, 2023). Regarding *Roe v. Wade*'s reversal, 78% of singles said they will change their dating and/or sex behavior, 20% said it will make them more hesitant to have sex, and 14% said it will make them more hesitant to date ("Singles in America"). Additionally, the top 3 ways respondents shared about how the decision would change their dating lives would be more condom use, more sex hesitation, and more fear of pregnancy ("Singles in America"). For Midwest respondents, 2 out of 3 single women said they would not date a partner who had opposing views on abortion ("Singles in America" study, 2022).

I believe this question about how the *Dobbs v. Jackson* ruling will impact the dating patterns of generations of Americans, especially for those who grew up with right to abortion, is important. While I could not find a dataset for post-*Dobbs* dating patterns, it is worth analyzing dating patterns before the ruling to compare. Therefore, I will be looking at a dataset of thousands of online dating profiles back in 2004-2005 to answer my research question: Is educational attainment associated with preferring to date someone who does not want kids? Specifically, is having graduated from college associated with having this preference?

DATA

The data set for this research project is called “Yahoo Personals Dating Preferences Study - Los Angeles, New York, Chicago, Atlanta, 2004-2005” which I retrieved from the Inter-University Consortium for Political and Social Research (ICPSR) website in October 2023. Cynthia Feliciano and Belinda Robnett, both from the University of California- Irvine, were the study’s principal investigators. The description of the dataset on ICPSR says the study, “sought to examine the dating preferences of online daters in four major metropolitan areas: New York, Los Angeles, Chicago, and Atlanta. Internet daters’ profiles of self-identified Asian, Black, Latino, and White men and women seeking opposite-sex dates were collected and coded from Yahoo Personals, which was the most popular national online dating website in 2004 and 2005. “Yahoo Personals”, 2016.)

Additionally, the sample section of the study’s page on ICPSR (2016) states, “Two hundred profiles each from 18-50 year old self-identified Asian, Black, Latino or White men and women seeking opposite-sex dates living within 50 miles of New York, Los Angeles, Chicago or Atlanta were collected and coded, for a total sample size of 6,070.” The targeted sample size was 6400 where the most recent 200 posted or edited profiles were selected within each ethnicity/gender/city category (200 male profiles + 200 female profiles per ethnic group = 400, 400 profiles* 4 ethnic groups = 1600, 1600* 4 metropolitan areas= 6400 total profiles). The sample is smaller than 6400 because of duplicates and 200 fewer Latina women and Asian male profiles in Atlanta (2016). When I uploaded the data from ICPSR, there were 6078 rows of data. Furthermore, to answer my research question, I removed 184 profiles that did not have education data and 24 rows that did not have data for the profile’s height. This left my data frame for analysis with 5870 observations. I also changed most of the variables from character variables to factor variables.

Data was collected on self-reported user characteristics (like height, age, body type, ethnicity, educational status, desire to have kids) and on their dating preferences (what characteristics they are looking for in a potential partner). Some dating-preferences characteristics include date’s minimum and maximum height, date’s body type, date’s age, date’s employment status, date’s desire to have kids. More often than not, the types of variables collected for user profiles mirrored the ones collected for the date’s characteristics. For my analysis, a profile’s characteristics are pre-treatment variables and the date preferences are post-treatment variables.

For my research question (“Is educational attainment associated with preferring to date someone who does not want kids? Specifically, is having graduated from college associated with having this preference?”), my treatment variable was if a profile had self-reported on whether they had graduated from college or not. There are 6 options for the educational attainment variable: “postgraduate”, “college graduate”, “some college”, “high school graduate”, and “some high school”. Profiles with either the first 2 options are my treatment

group (“YES” for obtaining a college degree) and profiles with any of the last 3 are my control group. To conduct my analysis and maintain the original integrity of the data, I created a binary indicator variable, with the code 1 for “YES- college degree obtained” and 0 for “NO – no college degree obtained”. The treatment group is the 3462 observations that had college degrees and the control group is the 2408 observations that did not have college degrees.

My outcome variable, Y , is also binary: having the preference to date someone with no kids with 0 representing “No – The profile does not want to date someone who does not want kids” (or can be thought of as “The profile wants to date someone who wants kids”) and 1 representing “Yes – The profile does want to date someone who does not want kids”. My Y_1 is the profile having this specific dating preference”. My Y_0 , or counterfactual, does not have this explicit preference.

Some descriptive charts on the raw data are below in Figures 1, 2, and 3.

Figure 1.

Figure 2

Figure 3.

ESTIMANDS

The estimand I will be estimating will be the Average Treatment Effect on the Controls (the ATC). I am analyzing this estimand because I have 1054 more treatment group observations

(users who self-reported having obtained a college degree) than control group observations (users who have not obtained a college degree). The control group is now also called the ‘inferential group’ because we are making inferences about them when we are estimating effects. Therefore, the effect we estimate will only apply to those in the control group, not the treatment group. The effect could be different in the treatment group and that effect would then be called the Average Treatment Effect on the Treated (the ATT).

The notation for ATC, or getting the effect of the treatment on the controls, is:

$$E[Y(1) - Y(0) | Z = 0] = E[Y(1) | Z = 0] - E[Y(0) | Z = 0]$$

Commented [MS2]: Use readr for this

This means that for every observation in the control group, we subtract the hypothetical $Y1$ observation from the observed $Y0$ observation. The $Y1$ is hypothetical because that is what the outcome value would be for that control observation if they had received the treatment in a parallel universe. Since we cannot see what would have happened to the control observation in this universe where they received the treatment, which is getting a college degree, the $Y1$ when it comes to the ATC is called a counterfactual [outcome]. We cannot see it at the same time as the observed outcome for the control group, which is $Y0$.

If we take the average of all the differences between $Y1$ and $Y0$ in the control group, that is our ATC. Our formula looks like the following (RED for $Y1$, BLUE for $Y0$)

$$\begin{aligned} &E[Y(\text{PREFERS PARTNER TO NOT WANT KIDS}) - \\ &Y(\text{DOES NOT PREFER PARTNER TO NOT WANT KIDS}) | Z = \text{NON-CGRAD}] \\ &= \\ &E[Y(\text{PREFERS DATE TO NOT WANT KIDS}) | Z = \text{NON-CGRAD}] - \\ &E[Y(\text{DOES NOT PREFER DATE TO NOT WANT KIDS}) | Z = \text{NON-CGRAD}] \end{aligned}$$

METHOD

The causal inference method I am using is the propensity score method. In a dataset that has treatment and control observations, every observation gets a “propensity score” or “p-score”. A “propensity score” is basically a one number summary of the covariates (Gelman et al, 2020). It is the estimated probability that an observation receives the treatment or not. There are about 5 steps to implementing the propensity score method.

The first is deciding which variables are our confounders and what estimand or effect we are trying to estimate. A confounding variable is pre-treatment variable that predicts both the treatment and the outcome and not controlling for these in analysis may hinder our accuracy in estimating a true, unbiased treatment effect (pp. 385, 389). As stated above, the estimand for my analysis is the Average Treatment on the Controls. My list of confounders, which were all of

the pre-treatment covariates except for my treatment variable, include profile demographics like region, ethnicity, height, sex, age, smoking habits, drinking habits, participant's body-type, and language(s) the profile speaks. Other set pre-treatment covariates I include are the profile's marriage status, religion and how often they attend religious services, income, employment status and occupation, desire to have kids themselves, if they already have kids, living situation and environments (i.e. living with pets, kids, roommates, family and relatives), and political leaning.

Particularly with these latter set of covariates, it is likely some have been affected by the treatment (of obtaining a college degree), like occupation, income, and living situation to name a few. They could be considered post-treatment variables, therefore disqualifying them from our analysis. However, there is no data to indicate when a profile obtained their college degree or not. There is also no definite data if or when obtaining a degree changed these covariates. For example, people may have already been parents when they started working on their college degree, so they would have continued to be parents after receiving their degree. There is no way to know from the data I have. There is also a chance that the covariates, like the profile having the desire to have kids, might directly affect the outcome no matter what their college-degree status is. However, my logic when choosing these variables as pre-treatment variables is that they are characteristics of the profile that the profile already indicated/ knew about themselves *before* indicating that they wanted to find a partner who did or did not want kids. I hope that at least accounting for them in my analysis will help us get closer to the true treatment effect.

Next, we calculate our estimated propensity score probabilities. To do that, we regress the treatment variable on the confounders we chose above. Put another way, we estimate the treatment conditional on the confounders by entering them into regression models. The models typically used in this process are logit or probit regression models because the output of these models are probabilities, values from 0 to 1. At the same time, any model can be used if the output values are probabilities. Like with most causal inference methods, post-treatment variables and outcome variables cannot be used to calculate p-scores.

The third step, after the p-scores are estimated, is using the p-scores to restructure the data to make sure there is now overlap and sufficient balance in the data to estimate a treatment effect. There are multiple ways to restructure the data: matching the p-scores across treatment and control group with replacement, matching the scores without replacement, weighting observations based on how many times they appear in the data. When we match, every observation in our inferential group is "paired" with an observation from the other group based on similar their p-scores are. When matching is done with replacement, observations from the other group can be paired multiple times with an observation in the inferential group. For example, in regards to the ATC, if one treatment observation has similar p-score that is close to 2 different control observations, that treatment observation is paired twice, one time for each control observations: These control observations have the same treatment "partner" because

this treatment observation is the closest treatment observation to both of them (in the p-score space). The treatment observation is then given a weight of 2.

On the other hand, when matching is done without replacement, observations from the other group can only be paired once with an observation in the inferential group. That means if the inferential group is smaller than the other group, some observations in the other group will get thrown away. This is like the control and treatment groups in this Yahoo Personals Sample: because I have more treatment observations than control observations, not every treatment observation will be paired with a control observation and they will be removed from the restructure data, not to be used in analysis. In matching without replacement, all weights for the observations in the non-inferential group are either 1 or 0. Observations with weights of 0 are the ones that are removed.

For my analysis, I am using the matching with replacement method. It is easier to get matches from the treatment group to compare to the control group because there are more treatment observations to choose from.

In the fourth step, we compare the distribution of the scores between the treatment and the control group. We re-assess balance and overlap in the covariate space between the two groups. In other words, the p-scores from the treatment and control group are compared to see how different they are from each other. To make the comparisons, we look at the absolute standardized differences in means between confounders in the inferential and comparison group. Ideally, researchers should aim to get the absolute standardized mean differences as close to 0 as possible. The closer a value is to 0, the more balanced that confounder is between both groups. We look at the standardized mean differences instead of the regular means to put the mean comparisons on the same scale. If the research is not satisfied with balance in their current propensity -score model, the researcher should repeat Steps 2 through 4, adjusting their model, maybe including some interactions between confounders, and then reassessing balance and overlap until they are satisfied.

For my analysis, I strived to have my standardized mean differences not exceed 0.10. After about 30 versions of p-score models, I was able to achieve that goal in one of my models.

The fifth and final step is to estimate the treatment effect on the restructured data now that it has the ideal observations included (based on the matching method chosen) and the most overlap and balance possibly achieved. To estimate the effect, a linear regression model could include an argument for the weights. However, in my analysis, my outcome is a binary outcome (whether if someone has a preference to date someone who does not want kids or not). Therefore, I used a logistic regression model to estimate a treatment effect that is on the logit probability scale. However, my coefficients may not be collapsible.

The purpose of the propensity score method is to make the observational study data look like a randomization control trial (RCT). In a randomized control trial, on average, the treatment and the control groups have the same amount of observed and unobserved covariates in their

Commented [MS3]: Jennifer's note about collapsibility

Commented [MS4]: Look up more what this is about. This is from Jennifer's notes

respective samples (i.e. characteristics/ variables that the study measured/has data on and ones that were not measured). This hopefully will make the data look like it came from an RCT. That is because in RCTs, randomization is suppose to ensure that the treatment and control groups both have the same types of individuals so the researcher can make comparisons between them to determine if the treatment that the treatment group gets exposed to is the cause for any differences in the observed outcome between the two groups. The control group acts as a “counterfactual” state to the treatment group because they did not get exposed to the intervention. And it is vice versa for the treatment group: the treatment group acts as a “counterfactual” state to the control group.

That is why RCT’s are often referred to as the “gold standard” for determining causal effects: if all types of people (and their characteristics, lifestyles, backgrounds, beliefs, etc.), all have an equal chance of being in either the treatment and control group, than on average, each group would have an equal presence of all types of people within them. Each group starts off at the same baseline and then if exposure to the treatment is the only difference between the two groups, any difference detected in the outcome we want to measure can be solely attributed (in theory) to the treatment and exposure to it. The treatment is what caused the change.

ASSUMPTIONS

A lauded benefit of propensity score matching is that this method relaxes parametric (or linear) assumptions. However, my data set contains many factor variables where relaxing these assumptions is not necessarily needed. It is more of a concern for continuous variables. I am also assuming that there is no Stable Unit Treatment Value Assumption (SUTVA) violation. This means the treatment assignment of one observation does not affect the outcome of another observation: the outcomes are independent of each other.

I am also assuming ignorability, $E[Y(0) | Z=1, X] = E[Y(0) | Z=0, X]$, where all the confounding variables that could affect my outcome are equally distributed throughout my dataset and have been accounted for in my models. While I believe this dataset has measured some very important covariates that could be confounders for my outcome variable (like profile’s desire to have kids, occupation, employment status, income level, religion, how often they go to religious services; and ethnicity), I do not believe that *all* confounding variables have been accounted for and measured in the data set. For example, health status or chronic condition that could affect fertility (like endometriosis) or the profile’s preference for biological children or adoption. Still, to conduct my analysis, I must assume that some ignorability holds. Even for unobserved confounders not measured in the data, I am assuming that all confounders are properly controlled for and equally distributed on average between the treatment and control samples after propensity score matching. That way, I can unbiasedly estimate the effect.

Other assumptions I must make to conduct my analysis is that I have achieved sufficient overlap in the covariate space with my propensity score model. Given that the data had decent overlap to begin with before matching and the relatively large sample size, I believe there are some treatment and control units within every covariate and their distributions. In other words, there is some presence of each covariate in both my treatment and control group. I am also assuming I have specified the appropriate propensity score model to achieve adequate balance. I believe my propensity score model achieves adequate balance between the controlled and the matched treatment observations. The standard mean differences between the covariates before matching and covariates after matching all have an absolute value of 0.10 or below. The standard mean differences should be close to 0 and I believe 0.10 is a good threshold to make sure there is sufficient balance.

DIAGNOSTICS

Using the Matchit package, I assessed balance and overlap of the treatment and control groups' propensity scores before matching them. Figure 4 below shows a histogram chart of this assessment. There is overlap in all ranges of the p-score, however, it looks there is adequate balance in only 40% of the data.

Figure 4

To do a plausible analysis, better balance needs to be achieved so we will do that with p-score matching. Table 1 in the appendix reports the mean and variance statistics on this unmatched data, sorted in descending order of standard mean differences.

To achieve balance, I used nearest neighbor matching with replacement where I added all the confounders into a probit model with no interactions or variable-manipulation. Figure 5 shows that balance improved greatly with respect to the ATC with this matching method

Figure 5

Table 2 in the Appendix also showcases this improved balance. It is sorted in descending order of the matched eCDF Mean column values since they are equal to the absolute difference in means between the matched treated and the matched controls. These mean differences are now at 0.10 or below, a standard for determining adequate balance.

I would like to point out that the the age, height, and distance variables are the only variables where their matched eCDF values do not equal the absolute difference in means. They are continuous variables, so their matched standardized mean differences are what we should look at. However, their standardized mean differences seem proportional to their corresponding eCDF column values (in that their standardized mean differences are under 0.1), so we will just refer to eCDF values in this analysis.

Next, I simulated 20 other propensity score models, based on different covariate combinations, to see if I could achieve greater balance and overlap. The propensity score model that lowered my mean differences the most and improved my balance was a model that used all the confounders *with* an interaction between the profiler already having kids and the profiler wanting kids. Below in Figure 6 is the balance and overlap plot from this simulation.

Figure 6

These standard differences are in Table 3 (Appendix). However, there only seems to be slight improvement between the mean differences from my first model and this “interaction” model: The interaction in the latter does not lower the absolute differences greatly. Still, it maintains them at 0.10 and below.

RESULTS

After choosing the propensity score model with the interaction, I ran a logistic regression model on my restructured data where treatment units were matched with replacement to every control observation. One thousand twenty-eight (1028) treatment units were matched to 2408 control units.

Next, I included an argument for weights in my logistic regression model to account for the weighted treatment observations. Below is my final model to estimate the probability of a profile wanting to date someone who does not want kids.

Date-Does-Not-Want-Kids = $(\beta_1 \text{ Graduation Status} + \beta_2 \text{ U.S. Region} + \beta_3 \text{ Sex} + \beta_4 \text{ Age} + \beta_5 \text{ Ethnicity} + \beta_6 \text{ Marital Status} + \beta_7 \text{ Body Type} + \beta_8 \text{ Height} + \beta_9 \text{ Smoking Habits} + \beta_{10} \text{ Drinking Habits} + \beta_{11} \text{ Lives Alone} + \beta_{12} \text{ Lives with Kids} + \beta_{13} \text{ Lives with Parents} + \beta_{14} \text{ Lives with Pets} + \beta_{15} \text{ Lives with Roommates} + \beta_{16} \text{ Lives with Family} + \beta_{17} \text{ Lives in a Party like environment} + \beta_{18} \text{ Has Kids} +$

$$\beta_{19}\text{Wants Kids} + \beta_{20}\text{Employment Status} + \beta_{21}\text{Occupation} + \beta_{22}\text{Income} + \beta_{23}\text{Religion} + \beta_{24}\text{Amount Attends Religious Services} + \beta_{25}\text{Political Leaning} + \beta_{26}\text{Speaks English} + \beta_{27}\text{Speaks French} + \beta_{28}\text{Speaks German} + \beta_{29}\text{Speaks Italian} + \beta_{30}\text{Speaks Spanish} + \beta_{31}\text{Speaks Portuguese} + \beta_{32}\text{Speaks Dutch} + \beta_{33}\text{Speaks Chinese} + \beta_{34}\text{Speaks Japanese} + \beta_{35}\text{Speaks Arabic} + \beta_{36}\text{Speaks Russian} + \beta_{37}\text{Speaks Hebrew} + \beta_{38}\text{Speaks Hindi} + \beta_{39}\text{Speaks Tagalog} + \beta_{40}\text{Speaks Urdu}) * \text{p-score weights}$$

At the same time, the standard errors in my output can be off. To correct them (and in turn my estimate) I used the `sandwich` function. The resulting coefficient and standard error were -0.144 and 0.109, respectively.

Commented [M55]: Put why I did this

Based on this output, assuming SUTVA, ignorability, balance and overlap assumptions hold, the average treatment effect on the controls is -0.144 in log odds or logit. Because our coefficient is negative, that means that when a person obtains a college degree, there is a slightly lower probability that that person will have the preference to date someone who does not wants kids.

If we convert this log-odds coefficient to just odds, the result is 0.866. We could interpret this as if people in the control group had obtained college degrees, their odds of desiring a partner who does not want kids would be 0.866. Or alternatively, they have about 13.4 lower odds of having that preference as compared to not having that preference. Because the odds are less than 1, the chances or likelihood that they would have that preference lowers.

We can also interpret this result as probability. If we convert our model's log odds coefficient (-0.144) to a probability, we get 46.403%. This means that had people in the control group received a college degree, their preference to date someone who does not want kids would be lower than 50%, or lower than a 50-50 chance. Therefore, the alternative (to not date someone who does not want kids/ to date someone who wants kids) would have a higher probability because it would be above 50%: about 53.6% in this case.

I also ran another logistic regression model *without* weights for comparison. Continuing to use the `sandwich` function, the average treatment effect on the controls for this model is -0.076 and the standard error is 0.129. In odds, this effect is 0.927 and as a probability is 48.1 %. In this model, had people in the control group received a college degree, the probability that they would prefer to date someone who does not want children is a little higher, specifically 1.697% higher. The effect of obtaining a college degree on this dating preference is smaller in this model than in my propensity score model. However, the difference in effect between these two models is probably negligible.

DISCUSSION

In both my propensity score model and logistic regression model, having a college degree has a negative effect on the preference to date someone who does not want to have kids: having a college degree lowers the probability of having this preference. On the other hand, it could be said that having a college degree may slightly increase the probability that a person would prefer to date someone who wants kids.

However, because the ATC coefficients from both models are small, the effect of having a college degree on the preference to date someone who does not want to have kids is probably very small amongst this sample of Yahoo Personal users. Degree status likely does not have a major impact on this preference for users.

As stated before, I am not sure if I can assume complete ignorability where all my confounders have been adjusted for. I might have some hidden bias or omitted variable bias because of some unmeasured confounders, like chronic disease that could affect fertility.

Another limitation of my analysis is a characteristic of the data itself: Instead of specifying “Yes” or “No” on whether they preferred to date someone who did not want kids, many profiles left that answer blank. In fact, many college grad profiles and non-college grad profiles had “No Answer”, more than specific “Yes’s” and “No’s combined” (see Figure 3). With so many people not indicating a preference, it is hard to say if this effect is true for non-college grad profiles. It might improve my analysis to see if there are multiple treatment effects: one for those who say “Yes” and another for those who have “No Answer”.

However, hopefully this analysis may have shed some light on online dating patterns in the United States in 2004 and 2005. Particularly when it comes to the major life decision of choosing to have kids with a partner, having a college degree may have made people more open to the prospect of having children. Perhaps because of the economic benefits a college degree brings (on average). Also, now that online dating has dramatically increased in popularity and prevalence, looking at Yahoo Personals data from 2004 and 2005 is an interesting glimpse into the past when this new frontier in dating was in its infancy.

I will not extrapolate further, but it would be interesting to see how dating preferences have changed when the right to choose to bear a child is no longer fundamental in the United States of America. Further research comparing the dating patterns before and after *Dobbs v Jackson* is warranted. That way, we can get a better picture of how the landmark decision has affected U.S. dating patterns and the future goals of millions of Americans who now live with fewer rights.
